Abstract

It is well known that high energy data alone do not discriminate between asymptotic $\ln s$ and $\ln^2 s$ behavior of pp and $\bar{p}p$ cross sections. By exploiting high quality low energy data, analyticity resolves this ambiguity in favor of cross sections that grow asymptotically as $\ln^2 s$. We here show that two methods for incorporating the low energy data into the high energy fits give numerically identical results and yield essentially identical tightly constrained values for the LHC cross section. The agreement can be understood as a new analyticity constraint derived as an extension of a Finite Energy Sum Rule.

High precision low energy data represent a powerful constraint on the high energy behavior of hadronic cross sections via duality[1, 2]. The low energy data can be separated into two energy regimes, the resonance region and a region with energies in excess of a laboratory energy ν_0 where the resonances average into a featureless cross section in the sense of duality. These data represent powerful constraints on asymptotic fits to *high energy* data. Igi and Ishida[1] realized these constraints using a Finite Energy Sum Rule (FESR) which numerically averages the resonances, while Block and Halzen[2] simply required that the high energy amplitudes fit both the experimental cross sections and their derivatives at the transition energy ν_0 . Both methods discriminate between a $\ln s$ and $\ln^2 s$ asymptotic behavior of the asymptotic cross section, conclusively favoring the latter. They appear to be more selective than conventional fitting techniques[3].

In this note we will show that the constraints of Block and Halzen[2] derive from analyticity[4], as does the FESR(2) of Igi and Ishida[1]. The purpose of this note is to show that they are in fact equivalent, as confirmed by fitting the two apparently very different methods to a *common data set* of pp and $\bar{p}p$ cross sections[6].

Following Block and Cahn[7], we describe the high energy data in terms of real analytic amplitudes

$$f_+ = i \frac{p}{4\pi} \left\{ A + \beta [\ln(s/s_0) - i\pi/2]^2 + cs^{\mu-1} e^{i\pi(1-\mu)/2} - i \frac{4\pi}{\nu} f_+(0) \right\}, \quad (1)$$

for the crossing-even real analytic amplitude[8, 9] and

$$f_- = -\frac{p}{4\pi} D s^{\alpha-1} e^{i\pi(1-\alpha)/2}, \quad (2)$$

for the crossing-odd real analytic amplitude. If $\alpha < 1$, it parameterizes the Regge behavior of a crossing-odd amplitude which vanishes at high energies. A , α , β , c , D , s_0 and μ are real constants. The variable s is the square of the center of mass system (cms) energy, ν is the laboratory energy and p is the laboratory momentum. The real constant $f_+(0)$ is the subtraction constant[7] required at $\nu = 0$. From the optical theorem we obtain the total cross section

$$\sigma^\pm = A + \beta \left[\ln^2 s/s_0 - \frac{\pi^2}{4} \right] + c \sin(\pi\mu/2) s^{\mu-1} \pm D \cos(\pi\alpha/2) s^{\alpha-1} \quad (3)$$

with ρ , the ratio of the real to the imaginary part of the forward scattering amplitude, given by

$$\rho^\pm = \frac{1}{\sigma_{\text{tot}}} \left\{ \beta \pi \ln s/s_0 - c \cos(\pi\mu/2) s^{\mu-1} + \frac{4\pi}{\nu} f_+(0) \pm D \sin(\pi\alpha/2) s^{\alpha-1} \right\}, \quad (4)$$

where the upper(lower) sign refer to $pp(\bar{p}p)$ scattering.

In the high energy limit, $s \rightarrow 2m\nu$ where m is the proton mass, Eq. (3) and Eq. (4) can be written as

$$\sigma_0 \left(\frac{\nu}{m} \right) = c_0 + c_1 \ln \left(\frac{\nu}{m} \right) + c_2 \ln^2 \left(\frac{\nu}{m} \right) + \beta_{\mathcal{P}'} \left(\frac{\nu}{m} \right)^{\mu-1}, \quad (5)$$

$$\sigma^\pm \left(\frac{\nu}{m} \right) = \sigma_0 \left(\frac{\nu}{m} \right) \pm \delta \left(\frac{\nu}{m} \right)^{\alpha-1}, \quad (6)$$

$$\rho^\pm \left(\frac{\nu}{m} \right) = \frac{1}{\sigma^\pm} \left\{ \frac{\pi}{2} c_1 + c_2 \pi \ln \left(\frac{\nu}{m} \right) - \beta_{\mathcal{P}'} \cot \left(\frac{\pi\mu}{2} \right) \left(\frac{\nu}{m} \right)^{\mu-1} + \frac{4\pi}{\nu} f_+(0) \pm \delta \tan \left(\frac{\pi\alpha}{2} \right) \left(\frac{\nu}{m} \right)^{\alpha-1} \right\}, \quad (7)$$

where we have introduced the even high energy cross section $\sigma_0 \left(\frac{\nu}{m} \right)$, as well as the relations $A = c_0 + \frac{\pi^2}{4} c_2 - \frac{c_1^2}{4c_2}$, $s_0 = 2m^2 e^{-c_1/(2c_2)}$, $\beta = c_2$, $c = \frac{(2m^2)^{1-\mu}}{\sin(\pi\mu/2)} \beta_{\mathcal{P}'}$ and $D = \frac{(2m^2)^{1-\alpha}}{\cos(\pi\alpha/2)} \delta$. This transformation linearizes Eq. (6) in the real coefficients $c_0, c_1, c_2, \beta_{\mathcal{P}'}$ and δ , convenient for a χ^2 fit to the experimental total cross sections and ρ -values. Invoking Regge behavior, Igi and Ishida[1] fixed $\mu = 0.5$, which is the value we adopt in order to directly compare our method to their FESR(2) constraint.

At the transition energy ν_0 where we will match our high energy fits to the low energy data, we define

$$\begin{aligned} \sigma_{\text{even}}(\nu_0) &= \frac{\sigma^+(\nu_0) + \sigma^-(\nu_0)}{2} \\ &= c_0 + c_1 \ln(\nu_0/m) + c_2 \ln^2(\nu_0/m) + \beta_{\mathcal{P}'}(\nu_0/m)^{\mu-1}, \end{aligned} \quad (8)$$

where $\sigma^+(\sigma^-)$ are the total cross sections for $pp(\bar{p}p)$ scattering. Using the Block and Halzen value[2] for $\sigma_{\text{even}}(\nu_0)$, i.e., $\sigma_{\text{even}} = 48.58$ mb at $\nu_0 = 7.59$ GeV, we obtain the constraint

$$\begin{aligned} c_0 &= \sigma_{\text{even}}(\nu_0) - c_1 \ln(\nu_0/m) - c_2 \ln^2(\nu_0/m) - \beta_{\mathcal{P}'}(\nu_0/m)^{\mu-1} \\ &= 48.58 - 2.091c_1 - 4.371c_2 - 0.3516\beta_{\mathcal{P}'}. \end{aligned} \quad (9)$$

In brief, we have used the $\bar{p}p$ and pp cross sections at the transition energy $\nu_0 = 7.59$ GeV to anchor the asymptotic fit to the low energy data. The precise choice of ν_0 is not critical, as we will see further on. We will actually show further on that Eq. (9) is a consequence of analyticity.

To summarize, our strategy is to exploit the rich sample of low energy data just above the resonance region, but well below the energies where data are used in our high energy fit. At the transition energy ν_0 , the experimental cross sections $\sigma_{\bar{p}p}(\nu_0)$ and $\sigma_{pp}(\nu_0)$ are used to determine $\sigma_{\text{even}}(\nu_0)$ of Eq. (9). In turn, this constrains the asymptotic high energy fit so that it *exactly* matches the low energy data at the transition energy ν_0 , constraining the value of c_0 in Eq. (9). Local fits are made to data in the vicinity of ν_0 in order to evaluate the cross sections that are introduced in the above constraint equation, Eq. (9). We next impose the constraint Eq. (9) on a χ^2 fit to Equations (6) and (7). For safety, we start the data fitting at much higher energy, $\nu_{\text{min}} = 18.72$ GeV ($\sqrt{s_{\text{min}}} = 6$ GeV), well above ν_0 .

Given the previous analyses[1, 2] we only consider an asymptotic $\ln^2 s$ fit; the even amplitude parameter c_0 is constrained by Eq. (9), i.e., by c_1 , c_2 and $\beta_{\mathcal{P}'}$ and the experimental value of $\sigma_{\text{even}}(\nu_0)$. We then perform a simultaneous fit to the experimental high energy values of $\sigma_{\bar{p}p}$, σ_{pp} , $\rho_{\bar{p}p}$ and ρ_{pp} using six parameters: the even parameters c_1 , c_2 , $\beta_{\mathcal{P}'}$ and $f_+(0)$ and the odd parameters δ and α . Only the first 3 parameters are needed to describe the cross section.

We now derive a new constraint from analyticity[4], closely following Igi and Ishida's[1] derivation of the fixed-energy sum rule¹ FESR(2) which they used to constrain their high energy fit. They wrote the imaginary part of their even high energy amplitude expressed in terms of their dimensionless coefficients C_0, C_1, C_2 , and $B_{\mathcal{P}'}$ as

$$\text{Im}f_+(\nu) = \frac{\nu}{m^2} [C_0 + C_1 \ln(\nu_0/m) + C_2 \ln^2(\nu_0/m) + B_{\mathcal{P}'}(\nu_0/m)^{\mu-1}]. \quad (10)$$

After using the optical theorem, it yields the same cross section as σ_0 of Eq. (5) in the high energy limit ($p \rightarrow \nu$), if we make the substitutions $c_0 \rightarrow \frac{4\pi}{m^2}C_0$, $c_1 \rightarrow \frac{4\pi}{m^2}C_1$, $c_2 \rightarrow \frac{4\pi}{m^2}C_2$, and $\beta_{\mathcal{P}'} \rightarrow \frac{4\pi}{m^2}B_{\mathcal{P}'}$; note that the Igi and Ishida coefficients are dimensionless, whereas our coefficients c_0 , c_1 , c_2 , and $\beta_{\mathcal{P}'}$ have dimensions of mb. We next introduce the true even amplitude $F_+(\nu)$ (which, of course, we do not know), along with the odd super-convergent difference amplitude[5]

$$\nu \tilde{f}_+(\nu) \equiv \nu [F_+(\nu) - f_+(\nu)], \quad (11)$$

which, because of analyticity[5], satisfies the odd super-convergence relation

$$\int_0^\infty \nu \text{Im} \tilde{f}_+(\nu) d\nu = 0. \quad (12)$$

Note that $\nu \tilde{f}_+(\nu)$ satisfies Eq. (12), although neither the odd amplitude $\nu F_+(\nu)$ nor the odd amplitude $\nu f_+(\nu)$ alone necessarily satisfies it. Using Eq. (12), we now write

$$\int_0^\infty \nu \text{Im} F_+(\nu) d\nu = \int_0^\infty \nu \text{Im} f_+(\nu) d\nu. \quad (13)$$

Up until now, we have only used analyticity and the fact that the odd amplitude $\nu \tilde{f}_+(\nu)$ is super-convergent. However, super-convergence of $\nu \tilde{f}_+(\nu)$ also implies that $f_+(\nu)$, if it is a *good* representation of the high energy behavior, approaches sufficiently close to $F_+(\nu)$ at some transition energy ν_0 —taken as an energy somewhat above the resonance region—that the difference between these amplitudes is neglectable. Hence,

¹We have changed their notation to conform with that used in the present paper, replacing F by f , the energy N by ν_0 , and using capital letters for the real coefficients of their high energy parametrization, i.e., letting $c_0 \rightarrow C_0$, $c_1 \rightarrow C_1$, $c_2 \rightarrow C_2$ and $\beta_{\mathcal{P}'} \rightarrow B_{\mathcal{P}'}$. In what follows, m is the proton mass, p is the laboratory momentum and ν is the laboratory energy.

the integrand of Eq. (12) is essentially zero for energies above ν_0 , allowing us to truncate the integration of Eq. (13) at ν_0 , thus obtaining the finite energy relation

$$\int_0^{\nu_0} \nu \operatorname{Im} F_+(\nu) d\nu = \int_0^{\nu_0} f_+(\nu) d\nu = 0 \quad (14)$$

for sufficiently large ν_0 .

Applying the optical theorem to Eq. (14), we have the relation

$$\begin{aligned} \int_0^m \nu \operatorname{Im} F_+(\nu) d\nu + \frac{1}{4\pi} \int_m^{\nu_0} \nu p \sigma_{\text{even}}(\nu) d\nu &= \int_0^{\nu_0} \frac{\nu^2}{m^2} [C_0 + C_1 \ln(\nu/m) + C_2 \ln^2(\nu/m) \\ &\quad + B_{\mathcal{P}'}(\nu_0/m)^{\mu-1}] d\nu. \end{aligned} \quad (15)$$

Because $\int_m^{\nu_0} \nu p \sigma_{\text{even}}(\nu) d\nu = \int_0^{p_0} p^2 \sigma_{\text{even}}(p) dp$, where $p_0 = \sqrt{\nu_0^2 - m^2}$, this is the FESR(2) derived by Igi and Ishida which follows from analyticity, much as dispersion relations do.

Again using the optical theorem, we now rewrite Eq. (15) in a more general form as

$$\int_0^m \nu \operatorname{Im} F_+(\nu) d\nu + \frac{1}{4\pi} \int_m^{\nu_0} \nu p \sigma_{\text{even}}(\nu) d\nu = \frac{1}{4\pi} \int_0^{\nu_0} \nu^2 \sigma_0(\nu) d\nu. \quad (16)$$

Another constraint can be derived from the observation that above relation is satisfied for any ν_0 in the energy region above the resonance region, where the cross section is smooth. In particular, Eq. (16) is valid at $\nu_0 + \Delta\nu_0$, where $\Delta\nu_0$ is small, i.e., $0 < \Delta\nu_0 \ll \nu_0$. Subtracting Eq. (16) evaluated at ν_0 from Eq. (16) evaluated at $\nu_0 + \Delta\nu_0$ yields

$$\int_{\nu_0}^{\nu_0 + \Delta\nu_0} p \nu \sigma_{\text{even}}(\nu) d\nu = \int_{\nu_0}^{\nu_0 + \Delta\nu_0} \nu^2 \sigma_0(\nu) d\nu, \quad (17)$$

where $\sigma_{\text{even}}(\nu)$ is the value of the cross section at laboratory energy ν and $\sigma_0(\nu)$ is the cross section at ν obtained from the asymptotic amplitude. In the limit of $\Delta\nu_0 \rightarrow 0$, Eq. (17) yields the analyticity constraint,

$$\sigma_{\text{even}}(\nu_0) = \frac{\nu_0}{p_0} \times \sigma_0(\nu_0) \approx \sigma_0(\nu_0), \quad (18)$$

a relation good to $\sim 0.04\%$ for $p_0 = 10$ GeV, the value chosen by Igi and Ishida. Thus, we see that analyticity, which is the underlying fabric of the FESR(2) derived by Igi and Ishida[1] (Eq. (16)), *also* requires that the high energy even cross section $\sigma_0(\nu_0)$ of Eq. (5) must match the low energy experimental cross section $\sigma_{\text{even}}(\nu_0)$, if the parametrization of the high energy forward scattering amplitude is a *good* parametrization. Further, this result is *independent* of the value of the non-physical integral $\int_0^m \nu \operatorname{Im} F_+(\nu) d\nu$ needed to evaluate the FESR(2) in Eq. (16), even if it is very large.

Igi and Ishida[1] anchored their fit using Eq. (16), by numerically integrating $p^2 \sigma_{\text{even}} = p^2 [\sigma_{\bar{p}p} + \sigma_{pp}]/2$ over the low energy resonance region below $p_0 = 10$ GeV to obtain

$$\frac{1}{4\pi} \int_0^{p_0} p^2 \sigma_{\text{even}}(p) dp = 3403 \pm 20 \text{ GeV}. \quad (19)$$

Neglecting the error in Eq. (19) and approximating the left-hand integral (the integral over the non-physical region) in Eq. (15) as 3.2 GeV, they obtained the constraint

$$C_0 = 8.87 - 2.04C_1 - 4.26C_2 - 0.367B_{\mathcal{P}'}, \quad (20)$$

or, changing their dimensionless coefficients into our coefficients which have units of mb—by multiplying their coefficients by $\frac{4\pi}{m^2}$ —we rewrite the Igi and Ishida constraint as

$$c_0 = 49.28 - 2.04c_1 - 4.26c_2 - 0.367\beta_{\mathcal{P}'}. \quad (21)$$

This is the constraint that will be used in an alternative fit to the high energy data.

Before presenting our results, we comment on the “sieved” data that we will use for fitting[2]. It uses all of the data in the Particle Data Group[10] archive for $\bar{p}p$ and pp total cross sections and ρ -values with energies $\sqrt{s} \geq 6$ GeV. A robust $\ln^2 s$ fit was obtained which minimizes the Lorentzian squared[6], *before* imposing

the “Sieve” algorithm. The algorithm then proceeds iteratively to rid the data sample of the outliers, based on a maximum cut on the individual χ^2 of the i^{th} point, defined as $\Delta\chi_i^2$. Details are shown in ref. [2, 6]. A value of $\chi^2/\text{d.f.}=5.657$ was obtained for 209 degrees of freedom using the unscreened data[10]. This is to be compared to a value of $\chi^2/\text{d.f.}=1.095$ for 184 degrees of freedom, when using a $\Delta\chi_{i\text{max}}^2 = 6$ cut in the “Sieve” algorithm[6]. The “Sieve” algorithm eliminated 25 points with energies $\sqrt{s} \geq 6$ GeV ($5 \sigma_{pp}$, $5 \sigma_{\bar{p}p}$, $15 \rho_{pp}$), while changing the total renormalized χ^2 from 1182.3 to 201.4. The 25 points that were screened out had a χ^2 contribution of 980.9, an average value of 39.2. For a Gaussian distribution, about 3 points with $\Delta\chi_i^2 > 6$ are expected, with a total χ^2 contribution of slightly more than 18, not 980.9. This demonstrated the efficiency of the “Sieve” algorithm[6] in excluding outliers[2, 6]. The same data set with $\Delta\chi_{i\text{max}}^2 = 6$ and $\sqrt{s} \geq 6$ GeV is used in the present analysis.

Table 1 shows the results of a 6 parameter χ^2 fit constrained by FESR(2) and, alternatively, by the analyticity constraint that matches σ_{even} at ν_0 . The resulting χ^2 have been renormalized[6] for the cut $\Delta\chi_i^2(x_i; \alpha) = 6$. Both fits are excellent, each with a renormalized χ^2 per degree of freedom slightly less than 1.

Parameters	$\sigma \sim \ln^2 s, \Delta\chi_{i\text{max}}^2 = 6$	
	FESR2 Fit	“Analyticity” Fit
Even Amplitude		
c_0 (mb)	36.68	36.95
c_1 (mb)	-1.293 ± 0.151	-1.350 ± 0.152
c_2 (mb)	0.2751 ± 0.0105	0.2782 ± 0.105
$\beta_{p'}$ (mb)	37.10	37.17
μ	0.5	0.5
$f(0)$ (mb GeV)	-0.075 ± 0.67	-0.073 ± 0.67
Odd Amplitude		
δ (mb)	-24.67 ± 0.97	-24.42 ± 0.96
α	0.451 ± 0.0097	0.453 ± 0.0097
χ_{min}^2	158.2	157.4
$\mathcal{R} \times \chi_{\text{min}}^2$	180.3	179.4
degrees of freedom (d.f.)	181	181
$\mathcal{R} \times \chi_{\text{min}}^2/\text{d.f.}$	0.996	0.992

Table 1: The fitted results for a 6-parameter χ^2 fit with $\sigma \sim \ln^2(s)$ and the cut $\Delta\chi_{i\text{max}}^2 = 6$, for the FESR constraint $c_0 = 49.28 - 2.04c_1 - 4.26c_2 - 0.367\beta_{p'}$ and the “analyticity” constraint $c_0 = 48.58 - 2.091c_1 - 4.371c_2 - 0.3516\beta_{p'}$. The renormalized[6] $\chi_{\text{min}}^2/\text{d.f.}$, taking into account the effects of the $\Delta\chi_{i\text{max}}^2$ cut, is given in the row labeled $\mathcal{R} \times \chi_{\text{min}}^2/\text{d.f.}$. The errors in the fitted parameters have been multiplied by the appropriate r_{χ^2} (see ref. [6]).

The $\bar{p}p$ and pp cross sections derived from the parameters of Table 1 are shown in Fig. 1a) as a function of the cms energy, $\sqrt{s}$, for both methods. The $\bar{p}p$ (circles) and pp (squares) data shown are the “sieved” set. The short dashed and dot-dashed curves are the analyticity constraint fits to the $\bar{p}p$ and pp data, respectively. The solid curve and dotted curves are the same for the FESR fit. The difference between the two fits is negligible over the energy interval $4 \leq \sqrt{s} \leq 20000$ GeV; they agree to an accuracy of about 2 parts in 1000. It should be emphasized that the FESR fit uses the experimental resonance data below $\sqrt{s} = 4$ GeV for evaluating the constraint of Eq. (21), whereas the analyticity constraint fit uses the even cross section at $\sqrt{s} = 4$ GeV for the evaluation of its constraint, Eq. (9), *i.e., the alternative fits do not share any data*. Both strongly support $\ln^2 s$ fits that saturate the functional growth of the Froissart bound.

In Fig. 1b) we show all of the $\bar{p}p$ and pp cross section data[10] in the cms energy interval 4 to 6 GeV, none of which was used in our high energy fit. Inspection of Fig. 1b) reveals that we could have imposed the analyticity constraint anywhere from 4 GeV to 6 GeV without modifying the result. Thus, our conclusions do not depend on the choice of ν_0 , the transition energy used in Eq. (8).

Figure 2 shows the fits for $\rho_{\bar{p}p}$ and ρ_{pp} as a function of the cms energy $\sqrt{s}$; the “sieved” experimental data

are shown for $\sqrt{s} \geq 6$ GeV. We conclude that the results are effectively the same for both fits and in good agreement with the experimental data. Accommodating ρ -values at lower energies allows one to constrain the cross section at higher energies by derivative dispersion relations, giving us additional confidence in our extrapolations.

Summarizing, the FESR method and the new analyticity constraint introduced here yield fits to $\bar{p}p$ and pp cross sections and ρ -values that agree to 2 parts in 1000 over the large energy interval $4 \text{ GeV} \leq \sqrt{s} \leq 20000 \text{ GeV}$. In particular, at the LHC energy of 14 TeV, the FESR fit predicts $\sigma_{pp} = 107.2 \pm 1.4 \text{ GeV}$ and $\rho_{pp} = 0.130 \pm 0.002$, whereas the analyticity fit predicts $\sigma_{pp} = 107.4 \pm 1.5 \text{ GeV}$ and $\rho_{pp} = 0.131 \pm 0.002$. We showed that this agreement was expected—it is numerical confirmation that analyticity, in its two guises, gives identical numerical results. Further, the fact that the renormalized χ^2 per degree of freedom in Table 1 is excellent, giving a high probability fit, means that the choice of our high energy even asymptotic amplitude of Eq. (5) *satisfies* the analyticity constraint. It did not have to—had we used a poor representation for the even asymptotic amplitude, forcing the fit to go through the even cross section data at $\sqrt{s} = 4 \text{ GeV}$ would have resulted in a very high χ^2 . This was demonstrated in references [2] and [1], where an asymptotic $\ln s$ parametrization was decisively rejected.

The fit of Block and Halzen[2] which additionally constrains the cross section differences, as well as derivatives of the cross sections at $\sqrt{s} = 4 \text{ GeV}$, for both pp and $p\bar{p}$, yields essentially the same cross section and ρ -value, but with smaller errors. Clearly, from analyticity considerations, this technique is equivalent to evaluating additional FESRs, but is much more tractable numerically. This new tool yields both robust and precise values for the total cross section at the LHC energy of 14 TeV, as well as at cosmic ray energies, allowing us to make the prediction that at the LHC[2], $\rho_{pp}(14 \text{ TeV}) = 0.132 \pm 0.001$ and $\sigma_{pp}(14 \text{ TeV}) = 107.3 \pm 1.2 \text{ mb}$.

Figure 1: a) The fitted total cross sections σ_{pp} and $\sigma_{\bar{p}p}$ in mb, *vs.* $\sqrt{s}$, in GeV, using the single constraint of Equations (9) for the analyticity fit and (21) for the FESR fit of Table 1. The circles are the sieved data for $\bar{p}p$ scattering and the squares are the sieved data for pp scattering for $\sqrt{s} \geq 6$ GeV. The short dashed curve and dot-dashed curves are the analyticity fits—the *even* cross section at 4 GeV was fixed—to the $\bar{p}p$ and pp data, respectively. The solid curve and dotted curves are the FESR fits to the $\bar{p}p$ and pp data, respectively. It should be pointed out that the FESR and analyticity curves are essentially indistinguishable numerically for energies between 4 and 20000 GeV. b) An expanded energy scale that additionally shows the cross section data that exist[10] between 4 GeV, where σ_{even} was fixed, and 6 GeV, the beginning of the fitted data. It should be emphasized that *none* of the data between 4 and 6 GeV were used in the fits. We note that that the fits go through all of the unused points, with the exception of the $\bar{p}p$ point at 4.2 GeV, which would have been excluded by the “Sieve” algorithm[6] because of its large $\Delta\chi^2_i$, had it been used.

Figure 2: The fitted ρ -values, ρ_{pp} and $\rho_{\bar{p}p}$, vs. $\sqrt{s}$, in GeV, using the single constraint of Equations (9) for the analyticity fit and (21) for the FESR fit of Table 1. The circles are the sieved data for $\bar{p}p$ scattering and the squares are the sieved data for pp scattering for $\sqrt{s} \geq 6$ GeV. The short dashed curve and dot-dashed curves are the analyticity fits—the *even* cross section at 4 GeV was fixed—to the $\bar{p}p$ and pp data, respectively. The solid curve and dotted curves are the FESR fits to the $\bar{p}p$ and pp data, respectively. It should be pointed out that the FESR and analyticity curves are essentially indistinguishable numerically for energies between 4 and 20000 GeV.
